Putting assumptions to the test: A meta-analytic review of gender differences in emotional intelligence and specific emotion abilities

Abstract: Are women more emotionally intelligent than men? Emotional intelligence (EI) is often colloquially ascribed to women, yet the extant empirical literature yields inconclusive results and EI theories are largely oblivious to gender as an explanatory dimension. To re-evaluate the literature, test key moderators, and develop stronger theory on EI, we examine whether and to what extent gender differences manifest in EI through a meta-analytic review of 1,279 articles comprised of 1,428 samples containing 609,278 participants drawn from published and unpublished work until December 31, 2023. The results suggest gender differences in general EI such that women appear to have higher EI on average, as well as more nuanced gender differences across specific emotional abilities, including some where there may be no difference. Women's advantage is stronger for other- than self-focused emotional abilities and varies by measurement type, with smaller differences in subjective than in performance-based assessments. Additionally, we find that contextual moderators, including leadership position, male-dominated industry, data collection year, participant age, and geographical region are associated with the presence, magnitude, and direction of gender differences, suggesting that gender differences in EI vary across contexts. Overall, these findings show that women hold advantages in many emotional abilities, but that gender differences in EI are contingent on the target of emotional abilities, measurement type, and context, informing future research and theory building.

Keywords: emotional intelligence, EI, gender, meta-analysis

Putting assumptions to the test: A meta-analytic review of gender differences in emotional intelligence and specific emotion abilities

Emotional intelligence (EI), defined as "recognition and use of one's own and others' emotional states to solve problems and regulate behavior" (Salovey & Mayer, 1990, p. 189), has attracted sustained scholarly attention since its introduction in the early 1990s. From the outset, EI has been established as a critical predictor of important life outcomes beyond traditional cognitive abilities, including psychological health (Schutte et al., 2007), well-being (Fernández-Berrocal et al., 2016) and academic performance (MacCann et al., 2020). Extending this broader relevance to the domain of work and organizations, EI has been cast as an important construct in organizational research (e.g., Côté, 2014; Joseph & Newman, 2010). High EI is associated with many advantages at work, such as increased job performance (e.g., Joseph et al., 2015), or improved coping with stress (e.g., Lea et al., 2019), and appears particularly relevant for interpersonal relationships, through improved communication (e.g., Mortillaro et al., 2013), negotiation outcomes (e.g., Jordan & Troth, 2002; Der Foo et al., 2004), or constructive conflict management (e.g., Schlaerth et al., 2013; Hopkins & Yonker, 2015). Most scientifically established models of EI converge on three core emotion abilities: recognition, understanding, and regulation of emotions (Joseph & Newman, 2010).

Despite its prominence, EI research continues to wrestle with conceptual and methodological challenges (e.g., Dasborough et al., 2022). Competing perspectives define EI either as an *ability* and a type of intelligence intersecting with *cognitive abilities* (e.g., Mayer et al., 2001), as a *personality trait* closely aligned with Mayer et al.'s theoretical model (e.g., Schutte et al., 1998), or a very broad construct resulting from a combination of *personality and abilities,* respectively (e.g., Bar-On, 2006; Goleman et al., 2002)*,* leading to inconsistent

operationalizations and measurement practices. Beyond such debates lies a less examined tension: EI is often perceived and discussed in implicitly gendered ways, despite gender rarely being integrated into EI theory itself.

Popular media outlets such as *Psychology Today* (Goleman, 2011) and *Forbes* (Rastegar, 2023) have featured articles claiming that women possess higher EI, and the broader field of emotion research has long grappled with gender stereotypes associating emotionality with femininity (e.g., Shields, 2002). Surprisingly, EI theorists have been mostly silent about possible gender effects, despite a substantial empirical literature. Existing evidence offers inconsistent results, with some studies finding that women score higher in general EI (e.g., Cabello et al., 2016; Day & Carroll, 2004), others suggesting that men may possess higher EI (e.g., Petrides & Furnham, 2000), and others that find no significant overall differences in EI between women and men (e.g., Meshkat & Nejati, 2017; Whitman et al., 2009). One of the most prominent accounts to consider gender is the meta-analysis of the cascading model of EI (Joseph & Newman, 2010), which in subgroup analyses included 68 independent samples and found that women score higher on performance-based EI measures ($d = 0.47$, $k = 14$), whereas no difference emerged on self-report measures ($d = 0.01$, $k = 39$). These results offer a first indication that women may score higher on performance-based EI measures. Joseph and Newman's (2010) meta-analysis, however, included only studies that measured job performance as an outcome variable and was therefore not designed to provide a comprehensive estimate of gender differences in EI more generally. As of yet, the question as to whether gender differences exist in EI has yielded no consolidated empirical or theoretical answer.

Leaving the assumption of women's greater EI unexamined has potential pitfalls. First, avoiding the question whether women in fact possess higher EI than men may discredit genuine

differences as unscientific, thereby understating a possible advantage of women. Second, over-emphasizing and simplifying differences may reinforce workplace stereotypes, leading women to potentially be assigned disproportionate responsibility for emotional and social tasks (e.g., Martell & DeSmet, 2001). For scientific practice, a more systematic investigation of gender and EI could provide a fresh perspective to integrate overlooked aspects (e.g., differentiating emotion abilities focused on the self versus others) from gender studies into EI theory, address longstanding debates, and thereby revitalize scholarship on EI.

The purpose of our study is to examine whether and how gender differences manifest in EI. To do so, we meta-analyze 28 years of empirical research on EI across 76 countries. We (1) assess whether gender differences exist for general EI and for the three established sub-dimensions, (2) hypothesize that the target of emotion abilities relates to gender differences (i.e. whether the target is the self, as for example, in self-management, or the other, as for example, in the recognition of the emotions expressed by an interaction partner) and (3) test whether contextual factors, such as holding a leadership position or working in a male-dominated industry, are associated with the size and direction of gender differences.

Socialization as a Mechanism for Gender Differences in Emotional Intelligence

Gender has been considered in numerous accounts relating to the emergence, experience, and expression of emotions. Ontologically, the construction of emotions can itself be seen as gendered. For example, one of the "bedrock beliefs" (Shields, 2002, p. 10) about emotion in Western cultures is that emotionality is stereotypically feminine. Women are assumed to experience more emotion, leading them to being stereotyped as overly emotional, or driven by their emotions (Brescoll, 2016). However, and despite it being popular belief, the claim that emotional experiences are fundamentally different for men and women is questionable and

contested (e.g., McRae et al., 2008; LaFrance & Banaji, 1992). What seems to be a driving factor for gender differences is the way in which emotions are expressed and responded to (e.g., Plant et al., 2000). Given that much of EI is about perceiving and responding to emotions, reflecting on gender in EI theory seems essential.

Theoretically, we may expect to find that gender differences on general EI may favor women, as EI can be developed and trained (Mattingly & Kraiger, 2019; Hodzic et al., 2018). Thus, socialization may affect the way in which EI and specific emotional abilities are developed. Socialization processes frame social and emotional norms, which integrate members into society (Mayer & Beltz, 1998). Gender scholars have pointed out that socialization may differ for different genders (e.g., Leaper & Friedman, 2007). Parents and peers from an early age treat girl infants differently compared to boy infants (e.g., Mondschein et al., 2000; Brody, 2000). Girls are more often encouraged to attend to emotional states, both their own and others', while boys are socialized toward emotional restraint, especially for vulnerable emotions such as sadness (e.g., Brody, 2000; Klimes-Dougan et al., 2007). Consequently, this may mean that the informal EI 'training' boys and girls alike receive through socialization processes and social expectations may lead them to develop different emotionally relevant abilities (e.g., Sanchez-Nunez et al., 2008), with girls receiving more emotion-focused training and thus ultimately developing higher EI.

Hypothesis 1a: Women score higher in general emotional intelligence compared to men.

To unpack gender differences, we suggest that a focus on the dimensions that make up EI may offer a more nuanced understanding. Similarly to cognitive ability, where on average, men have been found to perform better at visuospatial tasks, while women show higher verbal fluency (Kheloui et al., 2023), we examine gender comparisons at the dimensional level.

Emotion Recognition Ability

The ability to recognize emotions refers to "[…] how accurately and how fast individuals can express emotions and identify, detect and decipher aspects of emotional experiences and emotional displays" (Côté, 2014, p. 463). Self-focused emotion recognition draws on introspection (awareness of internal affective states), internal signal detection (identifying emotion-relevant bodily or cognitive cues), and pattern recognition (matching cues to emotion categories; Lane & Schwartz, 1987; Scherer & Moors, 2019; Konar et al., 2015). Other-focused emotion recognition relies more heavily on external signal detection and pattern recognition from cues, such as facial expressions, tone of voice, or body posture (Ekman & Friesen, 1971; Wallbott & Scherer, 1986).

Because societal expectations generally associate women with emotionality (except for displays of anger and aggression; Brody, 2000), we assume that women are socialized to identify and express their emotionality more, particularly for those emotions that are conducive to social relationships (e.g., Brody, 2000; Chaplin et al., 2005). Evidence found that daughters are encouraged more to elaborate on positive feelings compared to sons (Fivush, 1993). Mothers were also found to use a greater variety of emotion words when talking to their daughters compared to their sons (e.g., Dunn et al., 1987) and parents seemed to use more emotional utterance when discussing sad events with their daughters than with their sons (Fivush et al., 2000). Women may, from an early age, be increasingly exposed to situations in which they are expected to identify or describe how they feel. Because emotion vocabulary facilitates more precise mapping of cues to emotion categories (Lindquist et al., 2015), this early and repeated exposure to rich emotional language should strengthen women's ability to detect and label both their own and others' emotions.

Empirical results seem to support the idea that women possess higher emotion recognition ability compared to men. In adults, empirical evidence suggests that women were found to express emotions more strongly in their faces (Kring & Gordon, 1998). This difference appeared to hold across different emotions (Wagner et al., 1993). Women also self-reported a greater tendency to attend to their emotions (e.g., Gasper & Clore, 2000; Gohm & Clore, 2000). Additional performance-based evidence shows that women have been found to outperform men in the decoding of emotional non-verbal cues (e.g., Waaramaa, 2017; Collignon et al., 2010). A meta-analysis on the topic finds a moderate advantage of women in decoding nonverbal communication across 75 studies (Hall, 1978). Additionally, in their meta-analysis of 215 samples, Thompson and Voyer (2014) report differences of small magnitude favoring women in emotion recognition of non-verbal displays. Taken together, these results suggest that women may display an advantage in the ability to recognize emotions.

Hypothesis 1b: Women score higher in emotion recognition ability compared to men.

Emotion Understanding Ability

Emotion understanding is the ability to "[…] reason about various aspects of emotions, […] and identify connections between events and emotional reactions" (Côté, 2014, p. 466). It depends on conceptual knowledge of emotions and the ability to link emotional states with causes and consequences. Richer emotion vocabularies enable more differentiated emotion concepts, allowing for a finer-grained understanding (Barrett et al., 2007; Lindquist & Gendron, 2013). Traditionally, emotion understanding has been associated with tacit knowledge of emotions and has been found to correlate most strongly among the EI abilities with cognitive intelligence (MacCann et al., 2014; Joseph & Newman, 2010).

Women may develop an advantage in their knowledge about and understanding of emotions, as girls are more often engaged in such discussions and are encouraged to reflect on emotions (Fivush et al., 2000; Root & Denham, 2010), strengthening the mapping between events, emotions, and social norms. Increased conversations around emotions may facilitate learning and ultimately build a broader knowledge base. Because these discussions explicitly address the causes, consequences, and functions of emotions, they provide repeated practice in perspective-taking and causal reasoning, which are core components of emotion understanding. And indeed, in young toddlers, gender already seems to relate to emotion knowledge (but not to emotion regulation; Ornaghi et al., 2019; Reschke et al., 2024) and young girls (4-8 years) have been found to obtain more accurate appraisals of emotional images compared to boys (Stella et al., 2022). Similarly, research has shown that they also tend to articulate more nuanced explanations for the causes of emotions such as anger and sadness, both in themselves and in others (Hughes & Dunn, 2002).

Evidence from adult populations also suggests that women consistently outperform men on performance-based tasks assessing the complexity and differentiation of emotional knowledge, including the ability to anticipate how they themselves or others would feel in hypothetical scenarios (Barrett et al., 2000). Further evidence from studies using performance-based paradigms indicates that women possess more complex emotional knowledge even when motivational factors are experimentally controlled (Ciarrochi et al., 2005). In addition, performance-based tests assessing knowledge of nonverbal communication cues more broadly, including but not limited to emotional cues, have similarly shown that women tend to demonstrate higher levels of such knowledge than men, for example on the Test of Nonverbal

Cue Knowledge (TONCK; Rosip & Hall, 2004). Building on these results, we expect women to generally possess higher levels of emotion understanding.

Hypothesis 1c: Women score higher in emotion understanding ability compared to men.

Emotion Regulation Ability

Emotion regulation ability refers to "how well individuals can increase, maintain, or decrease the magnitude or duration of their or others' emotions" (Côté, 2014, p. 467). Regulating one's own emotions builds on self-recognition mechanisms (introspection, signal detection, pattern recognition) and draws heavily on executive functions, including planning, inhibitory control, and strategy implementation (Gross, 1998; Zelazo & Cunningham, 2007). Regulating others' emotions relies more on perspective-taking, social cognition, and the selection and execution of interpersonal strategies to influence others' emotions (Niven et al., 2009; Zaki & Williams, 2013).

Because display norms for emotions differ depending on gender, expressing certain emotions becomes natural and prototypical for some, while other displays of emotionality may be deemed as inappropriate (Shields, 2000; Shields, 2013). Boys may be encouraged to suppress certain emotions, particularly sadness, while girls are encouraged to maintain relational harmony through interpersonal regulation (Brody, 2000; Timmers et al., 1998; Tamres et al., 2002). Consequently, the regulation of emotions is likely expected of and practiced by both women and men, albeit in different ways.

Several studies have collected evidence that women are judged differently than men by others when expressing emotions. For example, while anger expressed by a man may lead to increased perception of status, the opposite is true for women (Brescoll & Uhlmann, 2008). Observers also expect successful managers' emotion expressions to align more closely with male

prototypes (Fischbach et al., 2015). Consequently, "[…] women may be labeled as more emotional than men in large part because they are seen as less able to *control the outward display* of their emotions compared to men" (Brescoll, 2016, p. 417). For men, the flipside of this perception may be restrictive emotionality (Jansz, 2000), reflecting a tendency to inhibit the expression of certain emotions. Kring and Gordon (1998) find that although men appeared more relaxed than women, they showed greater skin conductance reactivity, suggesting "more men than women were internalizers, and more women than men were externalizers" (Kring & Gordon, 1998, p. 698).

Overall, men may be more prone to down-regulate most emotions, while women may be penalized for expressing certain emotions like anger. These gendered display norms not only influence expression but also shape the type of regulation strategies each group practices most often. Over time, repeated use of such strategies constitutes informal 'training' that can strengthen ability in those domains. Both genders thus face strong expectations to regulate their emotions, albeit in different ways, leading us to expect that men and women are both knowledgeable and practiced in emotion regulation.

Hypothesis 1d: There will be no significant gender difference in emotion regulation ability.

The Target of Emotion Abilities

Originally, the foundational definition of EI explicitly distinguished between abilities that are focused on emotions of *oneself* or of *others* (see Salovey & Mayer, 1990), yet in the years since, this distinction has often been overlooked. Although many measures implicitly or explicitly contain both targets within their items, they are seldomly differentiated systematically. As Pekaar et al. (2020) noted, "[…] scholars typically use general EI scores that mask the unique role of self-focused EI (dealing with emotions of the self) versus other-focused EI (dealing with

the emotions of others) […]" (Pekaar et al., 2020, p. 3). Only recently have scholars begun to pay systematic attention to a difference in self- and other-focused emotion abilities (e.g., Schlegel & Mortillaro, 2019), and emerging evidence shows that self- and other-focused emotion abilities are meaningfully distinct (e.g., Pekaar et al., 2018; Schlegel & Mortillaro, 2019).

We suspect that this neglect of targets may help explain the inconsistent findings in gender comparisons of EI. Long-standing gender stereotypes associating women with warmth and communality (e.g., Eagly, 1987; Eagly et al., 2020) suggest they may be perceived and potentially socialized to excel in perceiving, accommodating, and regulating emotions *of others* (Alexander & Wood, 2000). Supporting this, parents discuss emotions with daughters using a more interpersonal focus that links emotional causes to social relationships and the reactions of other people than they do with sons (Fivush et al., 2000). Such interactions may give girls more practice in noticing, understanding, and responding to the emotional states of others, fostering relationally oriented emotional skills.

Consistent with this socialization pattern, large-scale, multi-rater assessments show that girls almost always outperform boys on social emotional competencies such as caretaking duties or supervision of children, regardless of their employment status (e.g., Biernat & Wortman, 1991, Calasanti & Bailey, 1991). At work, women can demonstrate more empathy, responsibility, and social competence (Romer et al., 2011). These skills align closely with the recognition, understanding, and regulation of others' emotions, central to other-focused EI. Taken together, the evidence suggests that if gender differences in EI exist, they are most likely to emerge for abilities oriented toward *others* rather than the *self*.

Therefore, we assume that it may very well be the case that women are not better at navigating emotions *per se* but are expected and socialized to better recognize, understand, and

manage the emotions of others than men. Failing to account for the target of emotion abilities may obfuscate meaningful nuance and risk perpetuating existing hegemonic inequalities, as the "types of EI that women are supposedly good at are not valued as much as the types of EI that men are supposedly good at" (Shields & Warner 2009, p. 174). Accordingly, we revive the original distinction of targets of EI, suggesting that women's advantage may be mainly driven by abilities oriented toward the emotions of others.

Hypothesis 2a: Women´s advantage in general EI will be greater for other-focused EI than self-focused EI.

If women's socialization emphasizes responsiveness to others' emotions, this advantage should be most evident in all EI sub-dimensions that are other-focused. Women may be better than men at recognizing others' emotions relative to recognizing their own. Socialization processes likely heighten sensitivity to external emotional cues. Consistent with this reasoning, meta-analytic evidence based on performance-based tests that assess the ability to infer emotions or mental states from subtle facial cues indicates higher accuracy among women than men (Kirkland et al., 2013). Even among adolescents, girls scored higher in identifying other's emotions and this link was mediated by higher self-reported empathy (Ibanez et al., 2013). Self-report data further indicate that women consistently rate themselves higher on both cognitive and affective empathy (Jolliffe & Farrington, 2006). Together, this suggests that women's advantage in recognition is more pronounced when the target is another person.

Hypothesis 2b: Women´s advantage in emotion recognition will be greater for other-focused ability than self-focused ability.

We also expect women to be better than men at understanding others' emotions compared to their own. Beyond recognizing an emotional display, understanding requires inferring its

causes, likely drawing on contextual and relational knowledge. Women, socialized to prioritize others' emotional states, may be more likely to seek contextual information. For example, when asked to choose between their own wishes and those of another person, women and men made similar choices, but women offered more empathy-oriented reasoning compared to men (Mills et al., 1989). In a meta-analysis on physician communication patterns, women physicians engaged in significantly more psychosocial question-asking and emotionally focused talk compared to their male colleagues (Roter et al., 2002). These behaviors align closely with the skills needed to understand others' emotions.

Hypothesis 2c: Women´s advantage in emotion understanding will be greater for other-focused ability than self-focused ability.

Finally, we expect women to be more skilled than men at regulating others' emotions than their own. Regulating others' emotions draws on relational goals, perspective-taking, and interpersonal strategies. Women have been found to place higher value on intimacy than men (Duck & Wright, 1993; Felmlee et al., 2012), and to report more relationship-oriented motives for regulating or expressing emotions (e.g., seeking comfort, maintaining harmony) compared to men (Timmers et al., 1998). Recent evidence suggests that social regulation (compared to individual regulation) of negative affect can act as a regulatory boost for women, buffering negative emotional responses, but not for men (Sahi et al., 2025). These findings suggest that while self-focused regulation may be practiced by both genders, women may be more adept at socially regulating others' emotions.

Hypothesis 2d: Women´s advantage in emotion regulation will be greater for other-focused ability compared to self-focused ability.

Context Effects on Gender Differences in Emotional Intelligence

A gendered perspective emphasizes that EI is contextually bound. Many gender theorists have moved away from viewing gender as a fixed trait and instead conceptualize it as a context-dependent enactment (Butler, 1990; McKinlay, 2010; West & Zimmerman, 1987, i.e., 'doing gender'). In this view, contexts that activate gendered expectations (such as work settings or social roles; Shields, 2013) should heighten any differences shaped by early socialization. In contrast, dominant EI frameworks often treat emotional abilities as decontextualized. Guided by this assumption, few EI studies include contextual moderators in their theorizing or measurement (Côté, 2014; Pekaar et al., 2020). Because emotions themselves are inherently situational (e.g., Greenaway et al., 2018), ignoring context may miss opportunities to refine EI theory (e.g., Ybarra et al., 2013; Côté, 2014). We therefore examine whether the manifestation of gender differences in EI varies across contextual factors: leadership, industry, age, time, and geography.

Leadership. Social Role Theory (Eagly, 1987) argues that gender differences should be larger in situations in which men and women occupy different roles. In contrast, for situations in which social roles are similar for men and women as no gendered expectations are placed on behavior, gender difference should diminish (Eagly, 1987). Building on this theoretical framework, we expect gender differences in EI to be more pronounced when women occupy roles that are traditionally ascribed to men. This may be of special relevance for professional roles that men and women hold at work, as gender expectations are oftentimes closely connected to stereotypical occupational roles (Eagly & Wood, 2012), and positions of power (Ragins & Winkel, 2011). Women have been found to be seen as less prototypical as leaders than men (Badura et al., 2018), and women's gender becomes more salient in gender-incongruent circumstances (Manzi & Heilman, 2021). If leadership is generally associated with men, then Social Role Theory suggests that gender identity of women, and consequently the abilities we

stereotypically ascribe to women, should be particularly salient when women hold such leadership positions. Consequently, we expect stronger gender differences in EI to emerge in samples of leaders, compared to samples of non-leaders.

Hypothesis 3a: Gender differences in EI and specific emotion abilities favoring women will be larger in samples of leaders compared to non-leader samples.

Industry. While leadership roles represent a micro-level context in which gender differences in EI are observed, we expect meso-level contextual factors to also play a role. Industries represent a broader gendered context within which companies and individuals act. Consequently, industries widely seen as male-dominated or masculine such as manufacturing (e.g., Cabrera et al., 2009), may make the gender identity of women especially salient. Thus, in line with Social Role Theory (Eagly, 1987), we expect that stereotypically female abilities gain importance for women and are required to come to the forefront within highly gendered industry contexts, thereby widening differences between men and women.

Empirically, women have already been found to be burdened when they work in masculine industries. One study found that women receive lower performance ratings compared to men in male-dominated settings, such as the military (e.g., Pazy & Oron 2001; Biernat et al., 1998) or within financial service firms (e.g., Lyness & Heilman, 2006). Similarly, women's effectiveness ratings as leaders were lower in contexts with higher shares of men (Eagly et al., 1995; Ko et al., 2015). The proportion of women employed in an industry was also found to moderate emotional experiences of feeling overwhelmed, tense, respected and confident (Taylor et al., 2022). Specifically, men reported feeling more respected and confident than women in industries with a lower proportion of women. Another study found that women in male-dominated industries reported higher levels of pressure compared to men and, in conjunction with an interpersonally

oriented leadership style, worse mental health (Gardiner & Tiggemann, 1999). Taken together, these findings indicate that gendered expectations and the relevance of EI for women differ by industry.

Hypothesis 3b: Gender differences in EI and specific emotion abilities favoring women will be larger in male-dominated industries compared to other industries.

Participant Age*.* Because gendered socialization begins early in life, we expect that gender differences in EI may not be static but instead grow stronger with age. Early experiences (e.g., differential encouragement to notice, discuss, and respond to emotions) may produce small differences in childhood that compound over time through repeated practice and reinforcement. By adolescence and adulthood, accumulated experience may lead to more pronounced gender differences, particularly in abilities where early socialization advantages girls (e.g., other-focused emotion skills). Thus, age may serve as a developmental amplifier of gender differences in EI.

Hypothesis 3c: Gender differences in EI and specific emotion abilities will increase as sample age increases.

Time. Gender differences may furthermore vary across macro-level contexts, such as the era in which they are observed. The term 'emotional intelligence' was coined in the early 1990s, yet gender roles have changed in the last 30 years (e.g., Dilli et al., 2019; Belingheri et al., 2021). The Gender Data Portal (The World Bank, n.d.) contains global data on different gender indices and shows, for example, that the proportion of seats held by women in national parliaments has steadily increased since 1997, indicating increased representation of women in the political sphere around the world. Recent data from the US suggests that gender inequality has reduced over time, as women have surpassed men in the numbers of receiving their doctoral degrees (England et al., 2020). At the same time, other indicators paint a less rosy picture of gender

equality, such as gendered occupational segregation and persistently lower wages, with authors even arguing that "women's progress relative to men has slowed, and in some cases, progress has stalled entirely" (England et al., 2020, p. 6993). Taken together, while gender roles have been subject to change in the last thirty years and an investigation of temporal variation on gender differences in EI is warranted, there is not sufficient evidence to make a directional prediction. We thus investigate the association of time with gender differences in EI in an exploratory fashion.

Research Question 1a: To what extent does time (data collection year) influence gender differences in EI and specific emotion abilities?

Geography. Furthermore, the gender norms that may result in gender differences in EI are themselves highly dependent on cultural context, as the nature and strength of these norms vary across the world (e.g., Fischer & Manstead, 2000; Alesina et al., 2013). Culture affects socialization practices of children, as well as what is considered to be intelligent behavior or role congruent behavior (e.g., Best & Williams, 2019). Furthermore, culture may also affect the way in which gender roles are constructed in relation to emotions. For example, one study found different relationships of positive and negative affect, depending on culture and gender. In independent-based cultures, women exhibited positive and negative affect to be opposed, while women in interdependent-based cultures showed dialectic relation and therefore a more harmonious co-existence of positive and negative affect. For men in both cultures, positive and negative affect were largely isolated and therefore mostly independent (Bagozzi et al., 1999). Therefore, the geographical origin of samples may be related to the extent to which gender differences manifest.

At the same time, some studies have found that EI varies across cultural contexts (e.g., Gunkel et al., 2014a; Shao et al., 2015), indicating that EI itself may also be prone to cultural differences. In particular, one study featuring samples from nine different countries found heterogeneous and inconsistent gender differences on all assessed emotion abilities (Gunkel et al., 2014b). If both gender roles and EI itself are affected by cultural context, we must then investigate how gender differences unfold across different regions in the world.

Research Question 1b: To what extent does geography (region of the world) influence gender differences in EI and specific emotion abilities?

Measurement Bias in Emotional Intelligence

To examine the stability of gender differences and the extent to which they vary across measurement approaches, we compare gender differences across different measurement strategies of EI. In research on EI more broadly, it has become a well-established meta-analytic practice to compare self-reported measures against performance measures to account for methodological effects (e.g., Martins et al., 2010; Joseph & Newman, 2010). Even though performance measures have been put forward as scientific gold standard (e.g., Côté, 2014), self-reported measures are commonly used, due to their practicality and ease of administration (O'Connor et al., 2019; MacCann et al., 2003). Both measurement types have potential pitfalls, with self-reported EI measures not being conceptually clean, and performance tests incorporating potentially culturally dependent stimuli (Zeidner et al., 2001). With regards to gender, the extent to which gender differences emerge may differ across measurement approaches.

Theoretically, the effect of self-reported measures compared to performance-based ones could work in two opposing directions, either exaggerating existing gender differences or obscuring them. On the one hand, self-assessment measures may further enhance existing gender

differences because they can fall prey to stereotypes. Self-reports of EI in particular are prone to bias and faking (e.g., Day & Carroll, 2008). Additionally, compared to momentary or concrete measures, broad and general self-assessments may be most susceptible to reproduce gender stereotypes (e.g., Barrett et al., 1998). Therefore, self-ratings may run the risk of increasing differences due to the pressure to conform to gendered expectations.

On the other hand, the opposite effect may be possible, such that self-assessments obscure actual gender differences because they are vulnerable to over- or under-confidence bias. Evidence suggests that people in general tend to be overly optimistic in their assessment of EI. This may be particularly true for those that are least skilled and may even persist in the face of explicit feedback (Sheldon et al., 2014). In related fields, men have been found to overestimate their cognitive abilities while women underestimated their own intelligence (e.g., Hogan, 1978; Furnham & Gasson, 1998). Thus, self-report measures of EI may obscure actual gender differences due to under- and over-confidence of women and men, respectively.

In sum, the way in which EI is measured (i.e., self-report vs. performance-based assessment) runs the risk of obscuring or possibly inflating true gender differences. In their meta-analysis, Joseph and Newman (2010) found initial support for the idea that women tend to underestimate their EI when self-reporting. Although based on a restricted sample size, they suggest that women score higher on performance-based measures, while self-report measures did not reveal significant differences between men and women. To better understand the role measurement plays in the presence, direction, and magnitude of gender differences in EI, we include measurement as a methodological moderator.

Research Question 2: Do gender differences in emotional intelligence differ by measurement type?

METHOD

Transparency and Openness

The present study was conducted in compliance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses 2020 Guidelines (Page et al., 2021) and the American Psychological Association (APA) Meta-Analysis Reporting Standards (MARS; Appelbaum, et al., 2018). Coding materials, the measure taxonomy, analytic code, the full dataset, and results from supplementary analyses are available in an online appendix hosted by the Open Science Framework (OSF; osf.io/xastg). We transparently report all data exclusions and sample sizes for each analysis. The design, analysis, and hypotheses were not pre-registered, but we did register a revised search and analytic plan as part of a revision before conducting the revised search and analyzing the full dataset (Hausfeld, 2025), which is available on the OSF project page (Hausfeld et al., 2026).

Systematic Search Procedure

For a visual representation of the search, screening, and coding procedures, see Figure 1. To capture the breadth of literature on gender and EI, we adapted and broadened search terms from prior meta-analyses on EI (e.g., Joseph & Newman, 2010; Miao et al., 2021; Miao et al., 2017). Initial searches were conducted in July 2023 using Web of Science and EBSCOhost (specifically, APA PsycBooks, Business Source Premier, APA PsycArticles, APA PsycExtra, and APA PsycInfo). No start date was imposed in order to capture all empirical evidence on EI available at the time of the search. During the peer-review process, the scope of the review was refined and the searches were repeated while keeping the temporal scope (i.e., including studies published through 2023). We searched the abstract field for: “emotional intelligence” OR “emotional abilit*” OR “emotional competenc*”, and required at least one of the following terms

anywhere in the record/full text: gender OR sex OR women OR woman OR female*. Results were limited to English and to scholarly document types (peer-reviewed journal articles and dissertations). On EBSCOhost, we excluded studies with clinical/psychiatric samples by filtering out records indexed under disorder-related subject headings (e.g., schizophrenia, bipolar disorder, major depressive disorder, autism spectrum disorder, PTSD), ensuring our dataset reflects non-clinical populations. Given the scale of the meta-analysis, forward and backward citation screening was not conducted, which we acknowledge as a limitation.

The final search generated 8,110 hits. Although the search terms yielded many unusable results (akin to fishing with dynamite per the clever metaphor of O'Boyle et al., 2023), we felt further restricting by journal or discipline would not deliver a representative, comprehensive, and systematic search by inadvertently excluding relevant articles, and thus impeding our chances of using a gender lens to address some of the entrenched conflicts among scholars of EI. Of the initial hits, 1,776 were identified as duplicates and thus excluded from the export. After duplicate removal, we screened the abstracts of the exported hits (k = 6,334) and removed articles from consideration based on the following criteria: (1) theoretical articles without empirical data (k = 239), (2) articles including a clinical sample (k = 331) and (3) articles not published in English (k = 15). The remaining dataset was then sought for full-text retrieval (k = 5,749). Of these records, k = 757 could not be retrieved using standard access routes (i.e., direct database access, institutional subscriptions, or web searches). To minimize potential bias, we expanded our retrieval efforts using a stepwise approach. Because most of these non-retrievable articles were dissertations, we first obtained full-access licensing to ProQuest Dissertations & Theses Global, which allowed us to retrieve 570 of 613 ProQuest-listed dissertations (k = 570; the remaining k = 43 were available only in abstract form on ProQuest). For non-retrievable records not published

in ProQuest (k = 144), we conducted targeted searches in collaboration with professional librarians, resulting in k = 93 additional full texts retrieved. Finally, for records that could not be obtained through ProQuest database access or librarian-supported searches, we contacted authors directly when contact information was available, yielding k = 3 additional full texts. Overall, these efforts reduced the number of non-retrievable studies to k = 91 records, resulting in a final set of k = 5,661 records available for full-text screening.

Insert Figure 1 about here.

We screened the full text of all 5,658 articles and included only those studies that reported gender-disaggregated data for EI measures that met our measure eligibility criteria. Specifically, we included measures that either provided an overall score explicitly labeled as emotional intelligence (or emotional competence) by the original authors or could be meaningfully aligned with the ability-based EI framework (as discussed in greater detail below). We included studies that met the following criteria (a) the study reported absolute EI scores for men and women or other relevant statistics (e.g., correlation coefficient) that could be used to calculate Cohen's *d,* (b) the difference was reported on a measure of EI that fit our inclusion criteria, (c) the sample was not clinical, and (d) original data was collected. For studies that appeared eligible but did not report gender-specific effect sizes, we contacted the corresponding authors to request the required information.

Of the eligible studies, k = 2,941 did not report sufficient information to calculate effect sizes. We were able to identify valid contact information for k = 2,845 corresponding authors, whom we contacted directly by email. Out of those, k = 151 authors provided data in response to our requests. Data from k = 118 of these authors could be incorporated into the meta-analysis,

whereas data from $k = 33$ authors could not be used because they met one or more predefined exclusion criteria (and are therefore reported among the exclusions below). After incorporating responses from corresponding authors, $k = 2{,}790$ studies still lacked computable effect sizes and were excluded due to lack of information. A further $k = 972$ studies were removed because they did not contain a valid EI measure (i.e., the measure did not meet our eligibility criteria, insufficient information about the measure was available, or the measure assessed team-level EI). We additionally removed studies that relied on single-gender samples ($k = 275$), did not collect original empirical data ($k = 221$), involved clinical populations ($k = 73$), were not published in English ($k = 36$), or fell into other exclusion categories ($k = 12$; including retracted articles, correction papers, and studies published after 2023). Our final included sample consisted of 1,279 articles.

Conceptual Decision for Ability-Model of Emotional Intelligence

We adopted the ability-based framework of EI as the primary organizing model because it has demonstrated greater conceptual clarity and psychometric robustness than trait-based, or mixed model approaches (e.g., Côté, 2014; Roberts et al., 2008; Mayer et al., 2008b). Trait EI, while popular in applied settings, has been criticized for conceptual heterogeneity and poor discriminant validity, often overlapping substantially with broad personality constructs. In contrast, the ability framework, grounded in the original four-branch model of Mayer and Salovey (1997), operationalizes EI as a set of cognitive-emotional skills that can be reliably measured, and can also be assessed through performance tasks. Subsequent research has converged on three core abilities (i.e., emotion recognition, understanding, and regulation) after the "use of emotions to facilitate thought" branch was found to show weak internal consistency and problematic construct validity (e.g., Palmer et al., 2005; Roberts et al., 2006). These three

abilities are not only conceptually distinct but also sequentially related in a cascading process (Joseph & Newman, 2010).

Despite these conceptual advantages, trait-based and mixed-model measures remain prevalent in the empirical literature on EI. Excluding such measures would risk discarding a substantial body of evidence relevant to understanding gender differences in EI, which is the primary focus of the present meta-analysis. Therefore, we adopted an inclusive measurement strategy. Specifically, we included all measures that, according to their original publication, reported an overall score explicitly labeled as emotional intelligence or emotional competence. In addition, we included measures that were theoretically grounded in the Mayer & Salovey (1997) ability model and explicitly developed to assess abilities within this framework, even if they did not provide an overall EI score. This inclusive approach ensured that we captured the broadest relevant evidence base, while still grounding our inclusion criteria in established theoretical definitions of EI. To integrate this heterogeneous set of measures within a coherent theoretical framework, all measures were systematically coded and mapped onto the three core abilities of the ability-based model. Details on the coding decisions and procedures are provided in the following section.

Coding Procedure

Coding was conducted by 5 trained coders including the first three authors, who supervised the coding process. After an initial training session and establishing inter-rater reliability (Cohen's kappa ranged from .94 to .97; Cohen, 1960), the coders independently coded articles. To ensure the quality and rigor of coding, the first and second author conducted checks (following the best practices discussed by O'Boyle et al., 2023), reviewing and cleaning the final

dataset before analysis. Further information regarding the coding process, including all coding categories, is available in the online appendix on the OSF project page.

Emotional intelligence. We systematically recorded all emotion-related ability measures used in the included studies. For each measure, we retrieved and reviewed the original measurement publication to determine whether it meets our inclusion criteria. Measures were included in the meta-analysis if they met at least one of the following criteria: (a) the original authors reported an overall score explicitly labeled as emotional intelligence or emotional competence, or (b) the measure was explicitly grounded in the ability model of emotional intelligence (Mayer & Salovey, 1997) and designed to assess one or more EI abilities within this framework. For example, the Bar-On Emotional Quotient Inventory (EQ-i; Bar-On, 1997) was included because it provides an overall EI score, even though the measure is not derived from the Mayer-Salovey ability model. The Situational Test of Emotional Understanding (STEU; MacCann & Roberts, 2008) was included because it assesses a specific emotional ability developed directly within the Mayer-Salovey framework, despite not providing an overall EI score. Measures such as the Emotional Intelligence Scale by Schutte et al. (1998) were included because they are explicitly derived from the Mayer-Salovey model and provide overall EI scores as well as ability-level scores. In contrast, measures such as the Toronto Empathy Questionnaire (Spreng et al., 2009) or the Cognitive Emotion Regulation Questionnaire (CERQ; Jermann & Van der Linden, 2006) were not included because they neither provide an overall emotional intelligence score nor are they theoretically grounded in the Mayer-Salovey ability model.

To ensure reliability and consistency of measure inclusion decisions, the first and third authors independently evaluated a subset of 189 measures at an advanced stage of the project. Agreement was assessed separately for each decision step: (a) whether a measure provided an

overall score explicitly labeled as emotional intelligence or emotional competence (Cohen's kappa = .98), (b) whether a measure was theoretically grounded in the ability-based EI framework and assessed one or more EI abilities (Cohen's kappa = .95), and (c) the final inclusion versus exclusion decision integrating both criteria (Cohen's kappa = .92). Any discrepancies were discussed and resolved by consensus. Throughout the remainder of the coding process, the third author supervised all measure inclusion and exclusion decisions to ensure consistent application of the criteria. Across the screening process, we evaluated a total of 515 distinct measures, of which 245 met at least one inclusion criterion and were retained for analysis.

Specific emotion abilities. For all included measures, we coded each scale or subscale to capture which specific emotional ability was assessed. To maximize inclusivity and ensure conceptual alignment with the ability-based framework, we undertook a detailed, multi-step process to classify each measure used in the included studies. For every included measure, we first sought to obtain the full set of original items from published manuals, validation studies, or publicly available sources. When the original item set could not be retrieved, we relied on sample items provided in the primary study or in other publications using the same measure. If neither original nor sample items were available, we based our classification on the measure's facet descriptions as reported by the authors. As a last resort, when no description was available, we inferred the likely construct from the factor or subscale name.

Classification followed the three-ability framework (emotion recognition, understanding, and regulation) based on operational definitions from the cascading model of Joseph and Newman (2010) and the detailed conceptual descriptions in Côté (2014). All coding decisions were made by trained coders based on this framework, and a complete coding table detailing the

classification of each measure, including the rationale for its placement in a specific ability category, is available in the supplemental materials. For each scale or subscale, we assessed whether the items primarily targeted a specific emotional ability. When more than half of the items within a scale were consistent with one of the three abilities, we assigned the measure to that ability category. Scales that did not clearly correspond to any specific emotion ability under the ability model were coded as no construct fit. All scales coded as no construct fit contributed only to analyses of overall emotional intelligence when included in a measure's total EI score, but were not used in any ability-specific analyses. As a robustness check, we re-ran the overall meta-analytic models using only the subset of measures for which we had access to the complete list of original items, which can be found in the supplementary material. This more conservative approach ensures that ability classifications were based exclusively on direct inspection of item content, eliminating any potential misclassification stemming from reliance on sample items, descriptions, or factor names.

Target of emotional intelligence ability. We created a category *target,* which classified whether the emotion ability measured focused on either *oneself, others, or both*. To code the target of a construct, the authors obtained and examined the items of each measure. Measures and subscales containing items that referred to emotion abilities directed at perceiving, understanding, or regulating the emotions of the respondents themselves, were coded as self-focused, and measures, in which items referred to emotion abilities targeting others, were coded as other-focused. Measures that included both types of items were coded as both. For measures where original items could not be obtained, categorization was based (in order of importance) on sample items, descriptions of measures, and measure or factor names (e.g., emotional self-awareness' from the EQ-i 2.0 was classified as focused on oneself; Bar-On, 2006).

Gender and emotional intelligence effect size. We recorded the reported effect size between gender and EI for every sample reported in each study and captured the coding of gender in the data (i.e., whether 0 = woman, 1 = man). All effect sizes were converted to Cohen's *d*, an effect size measure commonly used to report differences between groups, and coded such that positive values would indicate higher scores for women while negative values would indicate higher scores for men.

Contextual Moderators

We captured additional information regarding the sample of each primary study.

Leadership. We recorded the professional description of each sample to determine whether it consisted of individuals occupying formal leadership positions. Following prior meta-analyses on gender and leadership (e.g., Eagly et al., 1995; Paustian-Underdahl et al., 2024) we coded samples as *leaders* when participants were explicitly described as holding a leadership role based on their job description (e.g., leaders, executives, managers, directors, supervisors, principals). Samples were coded as *non-leaders* when participants were described as workers without formal leadership responsibility or when no leadership role was indicated (e.g., employees, workers, followers, subordinates). Samples including both leaders and non-leaders (e.g., leaders and followers) were coded as *mixed*, and samples for which leadership status could not be determined (e.g., married couples) were coded as *no information.*

Participant Age. To examine whether gender differences in emotional intelligence vary as a function of age, we first recorded the average participant age for each sample and modeled *mean age* as a continuous moderator. This approach provides a direct indicator of age, allowing us to examine whether gender differences change gradually across the lifespan. However, some studies did not report average age at the sample level or reported a single average age collapsed

across multiple subsamples that differed in age composition (e.g., child and adult subsamples combined). Therefore, as an additional indicator of age, we created a categorical variable distinguishing samples comprised entirely of children (i.e., all participants younger than 18) and samples comprised entirely of adults (i.e., all participants older than 18), results of which we present in the online supplement and use for robustness checks.

Industry. We coded all samples for industry based on the sample descriptions using the International Labour Organization's (ILO) List of Sectors (International Labour Organization, n.d.), assigning each sample to one out of eight broad industry sectors. When a sample did not clearly fit a single category, we coded it as *other* (no clear fit) or *mixed* (spanning multiple sectors). To then classify industries as male-dominated versus non-male-dominated, we reviewed prior research on occupational and gender segregation reporting gender proportions for different sectors (Borrowman & Klasen, 2020), and mapped this evidence onto our sector classification. Based on this mapping, we coded the following sectors as *male-dominated*: agriculture, food and forestry; manufacturing; energy and mining; maritime and transport; infrastructure and construction; and private services sectors. The remaining sectors were coded as *non-male-dominated*: public service, utilities and health; education and research; and other sectors. Because sector definitions in the occupational segregation literature did not align perfectly with ILO sector categories, we additionally validated our classification using employment statistics from the International Labour Organization's global labor force database (ILOSTAT, n.d.). Using aggregated counts of employed women and men across all available countries between 2000 and 2023, this validation confirmed that all sectors we classified as male-dominated were comprised of more than 50% male employees (e.g., energy and mining, 87.1% male); whereas sectors we categorized as non-male-dominated were comprised of less than 50% male employees

(e.g., education and research, 37.6% male). Detailed descriptive statistics with gender proportions by industry are reported in the online supplement.

Time. We coded the data collection year to capture time when it was explicitly stated in the study. If the data collection year was not provided, we estimated it by subtracting two years from the publication year, following a linear transformation approach common in cross-temporal meta-analyses (e.g., Oliver & Hyde, 1993; Twenge & Campbell, 2001; Zhang et al., 2022).

Geography. We captured geography by coding the country in which data were collected as specified in the description of the sample. When a single sample contained responses from multiple countries, we coded the sample as "international" and did not include it in comparisons based on geography. To create theoretically informed regional categories from the 76 countries represented in our dataset, we grouped North and Central American and European samples and compared them with samples from the rest of the world (Africa, Oceania, Asia, and South America). This decision was guided by cross-cultural research showing that North and Central American and many European societies tend to exhibit comparatively less strongly prescribed and rigid gender role norms than many other world regions (Williams & Best, 1990; Costa et al., 2001; Lomazzi & Seddig, 2020), which may relate to the magnitude of observed gender differences in EI and emotional abilities.

Methodological Moderators

Measurement Instrument. For each EI measure, we coded whether EI scores reflect objective test performance, or whether they are self-report or other-reported.

Analytic Procedure

Analysis was conducted with R version 4.3.2 (R Core Team, 2023) within RStudio (Version 2023.09.01 "Desert Sunflower"; Rstudio Team, 2020). We used the *metafor* package

(Viechtbauer, 2010) to conduct random-effects meta-analysis and meta-regression. The package *ggplot2* (Wickham, 2011) was used to create figures. We explicitly distinguish between planned and exploratory moderator analyses to address increased risk of committing Type I error associated with multiple comparisons (Pereira et al., 2023) in line with current best practices (e.g., Pigott & Polanin, 2020).

In addition to the overall random-effects models, we tested moderators using mixed-effects meta-regression models (random effects for residual heterogeneity plus fixed effects for moderators) estimated via REML in *metafor*. For categorical moderators, we entered the moderator as a factor (dummy coded) and interpreted regression coefficients as the difference in pooled effect sizes (Δd) between each category and the reference group; omnibus moderation was evaluated using the model's Q-test for moderators (QM) and, to account for statistical dependence among effect sizes from the same sample, we re-estimated inference using cluster-robust variance estimation (CRVE) with clusters defined at the sample level. For continuous moderators (data collection year and mean participant age), we mean-centered the variable and scaled it for interpretability (year expressed per 5-year unit; age expressed per 10-year unit), and the slope coefficient was interpreted as the expected change in effect size (Δd) per unit increase in the moderator. Across moderator analyses, we report QM and its p value from the mixed-effects model and report β, $SE(\beta)$, 95% CIs, and p values from CRVE-based F tests.

RESULTS

Influential Cases and Outliers: Sensitivity Analyses

Overall, heterogeneity in our meta-analytic results was high as evidenced by high I^2 values. This suggests "true" differences between the included studies beyond sampling error. High heterogeneity can be expected, as we include a wide range of studies and hypothesize

several moderators. That being said, we inspected the data closely for potential outliers and influential cases that may affect the results. As a first step, we visually inspected the distribution of effect sizes through histograms and scatter plots of effect size vs. sample size for each emotion ability. These plots showed the expected bell-shaped distribution, with a few larger and smaller effects but no obviously implausible values.

Next, we fit random-effects models (REML) for each ability and computed studentized residuals and influence diagnostics using the rstudent() and influence() functions in *metafor*. We examined (a) standardized residuals, (b) Cook's distances, and (c) leave-one-out changes in the pooled estimate. Across abilities, no effects exceeded conventional cutoffs (|studentized residual| > 3, large Cook's distance, or change in the pooled *d* of .01 when deleted), and the influence diagnostics did not flag a coherent set of extreme or overly influential studies. We also experimented with a conservative absolute-value rule (e.g., excluding effects with $|d| > 4$) and found that this removed either no effects or only a very small number (i.e., $k = 2$ across the full dataset), with negligible impact on the pooled estimates.

Given the absence of clearly aberrant values in the raw plots, the lack of influential cases according to studentized residuals and influence diagnostics, and the large heterogeneity in the data, we retained all effects for the primary analyses. Considering trimming the dataset adds complexity without altering the overall pattern of results, we treat these procedures as sensitivity checks and present all primary analyses based on the full (untrimmed) set of effects.

Meta-Analytic Estimate of the Gender and Overall Emotional Intelligence Effect Size

Do women and men differ in EI? Results of the random-effects meta-analysis for gender and general EI can be found in Table 1, where positive effect sizes indicate higher scores for women and negative effect sizes indicate higher scores for men. The meta-analytic effect size

estimate for gender and general EI was d = .15, and the 95% confidence interval excluded zero, indicating that women scored higher than men in general EI and providing support for Hypothesis 1a. This estimate is based on an analysis of 1,276 effect sizes from 1,085 samples. To account for the statistical dependence among effect sizes from the same sample, we applied cluster-robust variance estimation (CRVE). The pooled effect based on 1,085 independent clusters remained unchanged (d = .15, SE = .01, 95% CI = [.13 to .17], p < .001). Taken together, these results demonstrate robust support for a small gender difference in general EI in favor of women and girls.

Meta-Analytic Estimate of the Gender and Specific Emotion Abilities Effect Size

Next, we evaluated gender differences for specific emotion abilities (see Tables 2-5). Women and girls scored higher on most emotion abilities, such as emotion recognition (d = .15), emotion understanding (d = .22), and the measures that did not fit within the ability framework (d =.08). These results support our initial hypotheses, as women scored higher in emotion recognition (Hypothesis 1b) and emotion understanding (Hypothesis 1c) than men. Like general emotional intelligence, these results were robust to CRVE, with similar results for emotion recognition with 781 effects from 586 samples (d = .15, SE = .02, 95% CI = [.12 to .18], p < .001), emotion understanding with 335 effects from 263 samples (d = .22, SE = .02, 95% CI = [.19 to .25], p <.001), and measures not within the ability framework with 1,173 effects from 309 samples (d = .08, SE = .02, 95% CI = [.05 to .11], p <.001). For emotion regulation, there was a small effect favoring women and girls (d = .04), and this result held with CRVE with 966 effects from 664 samples (d = .04, SE = .02, 95% CI = [.00 to .07], p = .025). As we predicted no significant gender difference in emotion regulation, Hypothesis 1d was not supported, as a small advantage for women and girls emerged.

Insert Tables 1-5 about here.

Moderator Analyses of the Target of Emotion Ability (Self/Other)

Most included primary studies measured general EI using both self- and other-focused measures, resulting in fewer than expected samples that would allow comparison. For the few samples that examined self-focused (k = 26) or other-focused (k = 27) general EI, there appeared to be a larger effect in other-focused general EI in comparison to self-focused EI. While the effect for self-focused measures was d = .07, a mixed-effects meta-regression revealed that gender differences for other-focused EI did differ significantly from self-focused EI, but there was no difference between both-focused general EI and self-focused EI. The omnibus test for moderation $QM(2) = 3.10$, $p = .213$) was not significant, but the cluster-robust F-test indicated a significant moderation effect, $F(2, 1082) = 4.90$, p = .008. Compared to self-focused general EI (d = .07), gender differences in other-focused general EI were significantly larger (Δd = .18; see Figure 2), whereas both-focused measures (Δd = .07) did not significantly differ from self-focused (see Table 6). Together, these results support Hypothesis 2a, suggesting that women may see a more pronounced advantage in other-focused general EI compared to self-focused general EI.

For the specific emotion abilities, upon visual inspection of confidence intervals (Hunter & Schmidt, 2004), gender differences favoring women appear consistently larger for other-focused abilities than self-focused abilities. Women scored higher than men in other-focused emotion abilities, including other-focused emotion recognition (d = .18), emotion understanding (d = .25), emotion regulation (d = .25) and measures that did not fit within the ability framework (d = .25). Whereas for self-focused abilities, women's advantage appeared more modest (for emotion

understanding d = .19), indistinguishable from zero (for emotion recognition d = .04), or reversed (for emotion regulation d = -.07). To formally test our hypotheses, we first ran mixed-effects meta-regression models and then added CRVE. For emotion recognition (see Table 7), the omnibus test of moderation was significant ($QM(2) = 37.00$, $p < .001$), with other-focused emotion recognition (Δd = .14, $p < .001$) and both-focused emotion recognition (Δd = .21, $p <$ .001) showing significantly larger gender differences favoring women compared to self-focused emotion recognition (d = .04, p = .173). These patterns held when accounting for dependence using CRVE with 779 effects within 586 samples, supporting Hypothesis 2b.

Insert Figures 1-2 about here.

For emotion understanding (see Table 8), the omnibus test of moderation was not significant ($QM(2) = 4.15$, p =.125), and the comparison of the gender difference between other-focused emotion understanding (Δd = .06, p = .053) with self-focused emotion understanding (d = .19, $p < .001$) approached but did not reach levels of statistical significance. When accounting for dependence using CRVE with 322 effects within 255 samples, the results remained consistent, and thus we do not find support for Hypothesis 2c. We repeated this procedure for emotion regulation (see Table 9), and the omnibus test of moderation was statistically significant ($QM(2) = 161.49$, $p < .001$), and the magnitude of the gender difference between other-focused emotion regulation (Δd = .30, $p < .001$) and both-focused emotion regulation (Δd = .40, $p <$ .001) compared to self-focused emotion regulation (d = -.07, $p < .001$) was statistically significant. Women and girls saw an advantage for other- and both-focused emotion regulation, whereas there was a gender difference favoring men and boys for self-focused emotion regulation. This pattern of results held when accounting for dependence of effects using CRVE

with 966 effects from 664 samples, providing strong support for Hypothesis 2d. See Figure 3 for a visual representation of the moderation, featuring a random subset of k = 20 effects from each group.

For EI measures not fitting within the ability framework of emotional intelligence (Table 10), the omnibus test of moderation was statistically significant ($QM(2) = 58.50$, $p < .001$), and the gender difference for other-focused abilities ($\Delta d = .23$, $p < .001$) emerged as statistically significantly larger than self-focused abilities ($d = .02$, $p = .227$), but there was no difference in the magnitude of the gender difference for both-focused abilities ($\Delta d = .07$, $p = .126$) compared to self-focused abilities. These results were robust to CRVE for 1,167 effects nested within 308 samples. Overall, these results support Hypothesis 2b and 2d, and indicate that women and girls appear to demonstrate greater skill in other-focused emotion recognition and regulation compared to self-focused emotion recognition and regulation, whereas Hypothesis 2c was not supported as statistically significant differences between self- and other-focused emotion understanding did not emerge.

Insert Tables 7-10 about here.

Moderator Analyses of Contextual Factors

Leadership. To assess whether gender differences in EI and specific emotion abilities are strengthened by leadership responsibility, we compared adults occupying leadership positions with adults in non-leadership positions. We then followed with a series of meta-regressions and added CRVE to account for dependence within the data due to multiple effects from the same sample. For general EI, the omnibus test of moderation was significant ($QM(1) = 5.14$, $p = .023$) suggesting that gender differences favoring women were larger in leader samples compared to

non-leader samples, but the moderation did not hold when accounting for the 301 effects nested within 269 samples ($F(1,267) = 3.83$, $p = .052$). For emotion recognition, the omnibus test of moderation was significant ($QM(1) = 11.64$, $p < .001$) and this held when accounting for the 181 effects nested within 123 samples ($F(1,121) = 6.97$, $p = .009$), with gender differences in samples of leaders being statistically significantly larger ($\Delta d = .24$, $p = .009$) than gender differences in adult non-leader samples ($d = .13$, $p < .001$). For emotion understanding, leadership role did not significantly moderate gender differences, and this finding held when accounting for the 81 effects nested within 59 samples. For emotion regulation, however, the omnibus test for moderation for emotion regulation was also significant ($QM(1) = 7.48$, $p = .007$), but when accounting for the 233 effects nested within 146 samples, the moderation was no longer statistically significant ($F(1,144) = 3.46$, $p = .065$). Gender differences in samples of leaders appeared larger ($\Delta d = .20$, $p = .065$) compared to gender differences in adult non-leader samples ($d = .00$, $p = .950$), but again this difference in magnitude was not statistically significant when adding cluster robust standard errors. The significant differences in the magnitude of the relationship between gender and emotion abilities in leader and non-leader samples that did emerge were in the hypothesized direction, thus we find partial support for Hypothesis 3a.

Industry. To test Hypothesis 3b, we also compared the direction and magnitude of the gender difference in EI and specific emotion abilities in male-dominated industries compared to other industries. We began with a visual inspection of confidence intervals of the meta-analytic effect size estimates and then formally tested Hypothesis 3b with mixed effects meta-regression and CRVE to account for dependence within the data. For general EI scores, the estimate of gender effects favoring women was slightly smaller in male-dominated industries, but this

difference did not reach levels of statistical significance (see Table 6). However, and contrary to our expectations, the gender differences in some emotion abilities (specifically emotion recognition and emotion regulation) were considerably smaller in male-dominated industries compared to other industries. Visual inspection revealed a similar pattern for emotion recognition (d = .04, 95% CI = [-.07 to .14] in male-dominated industries compared to d = .22, 95% CI = [.16 to .28]), emotion understanding (d = .13, 95% CI = [-.06 to .32] compared to d = .20, 95% CI = [.13 to .28]), and emotion regulation (d = -.07, 95% CI = [-.17 to .03] compared to d = .10, 95% CI = [.04 to .17]). Thus, we conducted mixed-effect meta-regression models for each emotion ability and then added CRVEs to account for dependence in the data. For emotion recognition, the omnibus test of moderation was statistically significant ($QM(1) = 5.61$, p = .018), and when accounting for the dependence within the data of the 251 effects from 174 samples with cluster-robust variance estimation, the test of moderators remained significant ($F(1,172) = 8.56$, p = .004) and masculine industry emerged as a significant predictor of the magnitude of gender differences in emotion recognition, with samples of adults working in masculine industries exhibiting smaller gender differences (Δd = -.19, p = .004) compared to other industries (d = .22, $p < .001$).

For emotion understanding, neither the omnibus test of moderation in the mixed-effects meta-regression ($QM(1) = .46$, p = .497), nor the test for moderators accounting for dependence in the data due to the 109 effects from 83 samples was significant ($F(1,82) = .53$, p = .468) were significant. Thus, gender differences in emotion understanding appeared similar in masculine industries compared to other included industries.

Emotion regulation revealed a similar pattern of a smaller gender differences in masculine compared to other industries, with an omnibus test for moderation that narrowly met

conventional thresholds of statistical significance ($QM(1) = 3.91$, $p = .048$). Importantly, when accounting dependence in the data with 301 effects from 204 samples by adding CRVE, the evidence for moderation was stronger ($F(1,202) = 6.46$, $p = .012$). Masculine industries featured statistically significantly smaller gender differences in emotion regulation ($\Delta d = -.17$, $p = .012$) compared to other industries ($d = .10$, $p = .012$).

Thus, we find that the expression of gender difference in EI and specific emotion abilities, at least for emotion recognition and emotion regulation, may depend upon context, with gender differences being least pronounced in masculine industries, and more pronounced in other industries. This pattern of results does not support Hypothesis 3b as effects that emerged were in the opposite direction than expected, but these results do provide initial support to the idea of contextually shaped expression of gender differences in emotion abilities in terms of industry.

Participant Age. Do gender differences in EI vary by participant age? We conducted meta-regressions to examine the extent to which participant age accounts for variation in the magnitude and direction of gender differences in emotional intelligence, using mean-centered average participant age as a moderator, scaled in 10-year units so that the slope reflects the change in d per 10-year increase in average age. For general emotional intelligence, we found significant moderation ($QM(1) = 15.32$, $p < .001$), such that samples at the mean sample age (approximately 27 years) featured a gender difference of $d = .13$ ($p < .001$) favoring women, and each ten-year increase in average sample age is associated with a small increase in the magnitude of the gender difference favoring women ($\Delta d = .04$, $p = .001$). These findings held when accounting for dependence in the data, with 967 effects within 803 samples ($F(1,801) = 11.13$, $p = .001$).

For emotion recognition, the omnibus test for moderation was significant ($QM(1) = 31.13$, $p < .001$), where samples featuring an average age of about 27 reported a gender difference favoring women of $d = .13$ ($p < .001$), each ten-year increase in average sample age is associated with a $\Delta d = .06$ ($p < .001$) increase in the magnitude of the gender differences in emotion recognition favoring women. This finding held when accounting for dependence in the data, with 645 effects from 484 samples ($F(1,482) = 39.00$, $p < .001$).

For emotion understanding, age did not statistically significantly moderate gender differences ($QM(1) = .39$, $p = .535$). When accounting for dependence in the data for child compared to adult samples, with 294 effects within 227 samples, the test of moderation for average participant age remained statistically insignificant ($F(1,225) = .30$, $p = .584$). For emotion regulation, the omnibus test of moderation for continuous age ($QM(1) = .29$, $p = .593$) was not statistically significant. This remained the case when accounting for dependence in the data with 795 effects within 541 samples ($F(1,541) = .22$, $p = .640$). For emotion abilities not categorized within the ability framework, average participant age did not result in a significant test for moderation ($QM(1) = .97$, $p = .325$), and this held when accounting for the 837 effects nested within 223 samples ($F(1,221) = .73$, $p = .394$).

Taken together, these results provide initial evidence in support of socialization as a potential mechanism for the expression of gender differences in emotional intelligence, but the effects were not consistent across different emotion abilities. Specifically, increases in age were associated with increases in gender differences in general EI and emotion recognition, but age was not a significant moderator for gender differences in other emotion abilities. Thus, we find mixed evidence, providing only limited support for Hypothesis 3c.

Time. Does time affect the extent of gender differences in EI? We tested data collection year as a moderator of the relationship between gender and EI, finding significant moderation for general EI ($QM(1) = 51.22$, $p < .001$) robust to CRVE ($F(1,1083) = 47.34$, $p < .001$), such that, compared to data collected in the average data collection year of the sample (i.e., the year 2013; $d = .15$, $p < .001$) data collected five years later in 2018 (given the five-year scaling of the moderator slope) features smaller gender differences in general EI ($\Delta d = -.06$ $p < .001$). See Figure 4 for a visual representation of the moderating role of data collection year on general EI. The same pattern held for emotion recognition ($QM(1) = 13.27$, $p < .001$) and was robust to CRVE ($F(1,584) = 15.57$, $p < .001$), such that data collected in the average data collection year in the sample (2013) features a gender difference in emotion recognition favoring women of $d = .15$ ($p < .001$), but data collected five years later (2018) features smaller differences ($\Delta d = -.05$ $p < .001$). Data collection year initially emerged as a significant moderator of gender differences in emotion regulation ($QM(1) = 4.27$, $p = .039$) such that data collected more recently showed diminished gender differences, but this effect did not hold when accounting for the nested data structure of 966 effects within 664 samples ($F(1,662) = 2.42$, $p = .120$). Data collection year also moderated gender differences in emotion abilities not fitting the ability model ($QM(1) = 13.15$, $p < .001$) robust to CRVE ($F(1,307) = 9.41$, $p = .002$). At the average data collection year in the sample (2012) the estimated gender difference favored women ($d = .08$, $p < .001$). Data collected five years later (i.e., 2017) features smaller differences ($\Delta d = -.03$, $p = .002$). Data collection year did not significantly moderate the gender difference in emotion understanding.

Insert Figure 4 about here.

Geography. To examine global context as a moderator of EI and gender, we conducted subgroup analyses and meta-regression, comparing North and Central American and European samples with samples from the rest of the world, namely samples from Asia, Africa, South America, and Oceania. We find that region significantly moderates the gender difference of general EI ($QM(1) = 30.89$, $p < .001$), and this effect was robust to accounting for dependence in the data with 1,173 effects within 996 samples, ($F(1,994) = 22.90$, $p < .001$). North and Central American and European samples featured substantially larger gender differences favoring women and girls ($\Delta d = .13$, $p < .001$) compared to the rest of the world ($d = .06$, $p = .013$), where gender differences approached zero. Notably, the tests for region of the world as a moderator for emotion recognition, emotion understanding, and emotion regulation were not statistically significant. Gender differences in emotion abilities not fitting within the ability model did differ by geography ($QM(1) = 13.71$, $p < .001$), and this effect was robust to accounting for dependence in the data with 1,116 effects within 295 samples, as indicated by a significant test for moderators ($F(1,293) = 9.54$, $p = .002$). North and Central American and European samples featured larger gender differences favoring women and girls ($\Delta d = .10$, $p = .002$) compared to the rest of the world ($d = .01$, $p = .673$), which featured no gender differences in emotion abilities outside of the ability model.

Methodological Moderator: Performance Measures

To further explore how methodological factors are associated with variation in gender effects and answer our second research question, we compared performance measures of EI with non-performance measures. The most common type of non-performance measure was self-report, but we also include other-reports. In line with previous meta-analytic findings, performance measures of EI and its specific emotion abilities reveal substantially stronger

performance for women compared to subjective measures. An investigation of general EI revealed a significant moderation *(QM*(1) = 106.63, $p < .001$) robust to CRVE accounting for dependence in the data with 1,264 effects within 1,075 samples ($F(1,1073) = 82.48$, $p < .001$). Gender differences favoring women and girls were substantially larger for performance measures ($\Delta d = .28$, $p < .001$) compared to subjective measures ($d = .10$, $p < .001$).

A similar effect emerged for emotion recognition, with a statistically significant moderation ($QM(1) = 14.64$, $p < .001$), robust to CRVE ($F(1,576) = 25.42$, $p < .001$), showing substantially stronger gender differences favoring women for performance measures ($\Delta d = .15$, $p < .001$) compared to subjective measures ($d = .12$, $p < .001$). For emotion understanding, however, the gender differences favoring women did not statistically significantly differ by measurement ($QM(1) = .66$, $p = .415$), and this finding remained statistically insignificant when accounting for the nested structure of the data ($F(1,257) = .56$, $p = .454$). For emotion regulation, measurement again emerged as a statistically significant moderator ($QM(1) = 88.70$, $p < .001$), robust to CRVE ($F(1,654) = 102.51$, $p < .001$), with much larger gender differences favoring women for performance measures ($\Delta d = .35$, $p < .001$) compared to subjective measures ($d = -.02$, $p = .257$).

These results indicate that measurement type (performance vs. non-performance) is associated with the direction and magnitude of gender differences in EI and specific emotion abilities, where self-report measures may underrepresent women's abilities for general EI, emotion regulation, and emotion recognition compared to men, whereas there was not support for the idea that subjective measurement of emotion understanding misrepresents women's actual emotion understanding ability.

Insert Table 11 about here.

Exploratory Analyses

To further probe the finding that the gender differences in several emotion abilities was significantly moderated by data collection year, we conducted additional exploratory subgroup and meta-regression analyses (Table 11). First, for each emotion ability we re-estimated the year meta-regressions separately within key subgroups: performance vs. non-performance measures, child vs. adult samples, and North and Central American and European samples vs. samples from other regions. We then fit exploratory interaction models in which data collection year (centered and scaled so that one unit reflects a 5-year increase) was entered together with each moderator and their year X moderator interaction. All models used mixed-effects meta-regression with CRVE to account for dependent effect sizes. Because these analyses were not part of the original analytic plan, they are reported as exploratory and interpreted cautiously.

For general EI, the exploratory models reinforced the main finding that gender differences favoring women are smaller in more recent studies. While this trend appeared smaller in performance measures compared to non-performance measures, the difference in the slopes was not statistically significant while both year and measurement type remained significant, indicating the time moderation holds even when accounting for measurement type. In contrast, when examining whether the relationship between data collection year and gender differences in general EI differed in child compared to adult samples, we found that child samples showed a steeper decline in gender differences over time (β ($\underline{\Delta}d$) = -.11) compared to adult samples (β (Δd) = -.05) , and the slopes differed significantly as evidenced by a significant test for moderation ($F(3,921) = 22.17$, $p < .001$) and interaction coefficient (β (Δd) = -.06, $p = .012$). Notably, the main effect of data collection year remained statistically significant even when including the

interaction between age group and year (β (Δd) = -.05, p < .001). Data collection year effects were also negative in both geographical groups featured, and the difference in slopes did not reach statistical significance.

For emotion recognition, for both performance and non-performance measures, more recent samples featured smaller gender differences, and there was no statistically significant difference between their slopes. Similar to general EI, the strongest pattern of results for emotion recognition involved age group, as adult samples demonstrated a small decline in gender differences in emotion recognition over time (β (Δd) = -.04), whereas child samples showed a much steeper decline (β (Δd) = -.14). This difference in slopes was confirmed with a significant test for moderation (F(3, 490) = 11.29, p < .001) and a significant interaction coefficient (β (Δd) = -.11). Notably, the main effect of data collection year remained statistically significant when including the interaction of data collection year and age group (β (Δd) = -.04, p = .014). Again, year effects did not differ significantly by region.

For emotion regulation, overall year effects were weaker and less consistent. Despite a significant omnibus test of moderation for performance (QM(3) = 91.38; F(3, 652) = 36.50, p < .001), neither subgroup slopes differed reliably from zero and the interaction coefficient was also not statistically significant. In contrast, differences again emerged when comparing year effects for child and adult samples. Adult samples did not feature a slope distinct from zero (β (Δd) = -.01, p = .542), whereas child samples showed a clear decrease in gender differences associated with data collection year (β (Δd) = -.14, p < .001). The test for moderation (F(3,551) = 7.62, p < .001) and interaction coefficient (β (Δd) = -.13, p = .001) were both statistically significant (see Figure 5). Notably, when including the significant interaction effect, the main effect of year was

no longer significant as a predictor (β (Δd) = -.01, p = .543). Geographic region again did not interact with year in predicting gender differences in emotion regulation.

Taken together, these exploratory analyses suggest that gender differences in general EI and in emotion recognition are smaller in more recent data collections, and this effect largely holds for different measurement types and when accounting for geographic region. For general EI, emotion recognition, and emotion regulation, decreases in gender differences associated with time are consistently steeper in child samples than in adult samples.

Robustness Checks and Publication Bias

We evaluated potential publication bias and small-study effects using a combination of funnel plots, trim-and-fill procedures, and Egger-type regression tests for funnel plot asymmetry, all implemented with *metafor*. Funnel plots are available on the OSF project page. For each emotion ability, we first produced standard funnel plots of effect size vs standard error and examined them visually. For general EI, the funnel plot suggested some asymmetry, with a cluster of smaller studies showing relatively larger positive effects. An Egger-type regression of effect sizes on their standard errors confirmed statistically significant asymmetry (z = 3.79, p < .001). A trim-and-fill analysis, however, estimated zero missing studies on the left side of the funnel and did not change the pooled estimate (d = .15). This pattern suggests asymmetry may be driven more by heterogeneity and small-study effects than by a systematic absence of negative or null studies, but they do warrant some level of caution in interpretation.

A similar pattern emerged for emotion recognition, where Egger tests indicated significant asymmetry (z = 3.53, p < .001), but trim-and-fill procedures again imputed no missing studies on the left size. Adjusted pooled effects again did not differ (d = .15). For emotion understanding, in contrast, Egger's test did not indicate significant asymmetry (z = -1.02, p = .310). The trim-and-

fill analysis, however, suggested a substantial number of missing studies on the right side of the funnel (k = 64), indicating that there may be unobserved studies with larger positive effects. The adjusted pooled estimate after imputing missing effects was substantially larger (d = .31, k = 299) than the unadjusted estimate (d = .22, k = 335), suggesting that the observed effect for emotion understanding, if anything, may be underestimated. We therefore interpret the emotion understanding results with particular caution.

For emotion regulation, Egger's test indicated evidence for asymmetry (z = 4.49, p < .001), whereas trim-and-fill procedures again imputed no missing studies on the left side and the pooled estimate was unchanged (d = .04). Given the pronounced heterogeneity in emotion regulation associated with measurement type (e.g. performance vs. non-performance) and focus (e.g., self-focused regulation vs. other-focused regulation), our interpretation is that the observed asymmetry is likely driven by this heterogeneity and by a small number of performance-based studies with comparably large effects and smaller samples, rather than by systematic suppression of null or negative results.

Taken together, these diagnostics indicate some evidence of funnel plot asymmetry for general EI, emotion recognition, and emotion regulation, but trim-and-fill adjustments did not change these pooled estimates. For emotion understanding, trim-and-fill suggested that the observed estimate may be conservative, potentially underestimating the true gender difference favoring women and girls. Overall, there is little evidence for a large set of missing negative or null studies that would overturn our main conclusions regarding gender differences in general EI, emotion recognition, emotion understanding, and emotion regulation.

As an additional robustness check, we also compared gender differences in EI between samples featuring working adults compared to student samples, to be sure results for adults were

not driven entirely by student samples. For emotion recognition, student samples featured slightly smaller gender differences favoring women (see Table 7), but across all other emotion abilities, results were robust and did not differ between student and working adult samples.

DISCUSSION

We find that on average, women indeed showed higher general EI compared to men, but gender differences in EI are multifaceted and complex. Our findings thus add a new, gendered perspective to existing theoretical conversations in the field, and also propose two ways in which EI theory could be extended: first, by considering the target of emotion abilities, and second by systematically including micro-, meso-, and macro-level contextual moderators in EI research and theory building.

Gendered Implications of Existing Emotional Intelligence Research

Most fundamentally, our findings critically question the reliance on general scores in EI research, as general scores of EI—amongst other problems (e.g., Maul, 2012; Mayer et al., 2024)—may disguise nuanced differences between men and women's emotion abilities. Our findings show that the presence, magnitude, and direction of gender differences in EI vary between different emotion abilities. For example, women scored substantially higher than men on the abilities of emotion recognition and emotion understanding, whereas gender differences on emotion regulation were small. We thus echo the call for differentiation of emotion abilities (e.g., Elfenbein & MacCann, 2017; Dasborough et al., 2022), because separating the dimensions of EI is important for more nuanced and accurate representations of gender differences in EI.

Although meaningful, the gender differences we observed were generally small (e.g., d = .15 for general EI), consistent with meta-analytic evidence that most psychological gender differences, including in cognitive abilities, personality traits, and leadership behaviors, are

modest in size (Hyde, 2005; Zell et al., 2015). Small effects, however, are not trivial: even minor disparities can accumulate over time through everyday organizational decisions and social interactions, producing substantial gaps in outcomes such as promotions or leadership representation (Martell et al., 1996). These findings highlight a key duality. On one hand, the modest size of most effects cautions against essentialist interpretations of EI ("of course women are better at emotions") and aligns with the gender similarities hypothesis (Hyde, 2005), underscoring that gender differences are not uniform and depend on the specific EI ability and its context. On the other hand, women's near consistent advantage in other-focused abilities may represent an underutilized interpersonal resource across many social and organizational contexts, including leadership roles. Recognizing these strengths without reinforcing stereotypes offers opportunities to broaden leadership pipelines and better align individuals with roles that benefit from such abilities. A nuanced approach is therefore essential: one that leverages women's demonstrated strengths while remaining attentive to the social and contextual factors that may shape when and how these abilities are expressed.

Rediscovering the Target of Emotion Abilities

A key contribution of our work is our examination of the social dimension of gender differences based on gender theory, by systematically considering the target of EI abilities. We found larger differences favoring women in emotion abilities targeting *others*, particularly for general EI and the abilities of emotion recognition and emotion regulation. While our analyses focus on gender differences, they yield broader implications for how EI is conceptualized and measured and for how debates in EI research can be advanced.

Our results emphasize the importance of explicitly accounting for the target of emotional abilities in both theoretical models and empirical assessments of EI. Distinguishing whether

emotional abilities are directed at the self or at others may help refine existing EI frameworks and improve the construct validity of EI measures, particularly in light of recent work highlighting the conceptual and empirical separability of self- and other-focused emotion abilities (e.g., Schlegel & Mortillaro, 2019; Mortillaro & Schlegel, 2023). Differentiating targets of emotion abilities may further help clear the fog surrounding some contested patterns of results within the field. For example, differentiating between targets may further elucidate the relationship between EI and leadership (e.g., Antonakis et al., 2009; Dasborough et al, 2022) or creativity (e.g., Mayer et al., 2008a; Parke et al., 2015). Although, for example, other-focused emotion abilities could be particularly relevant for successful leadership behaviors, and self-focused abilities for being more creative, a failure to differentiate targets may obscure actual predictive effects of EI.

The distinction between abilities concerning "one's own and others' emotional states" (Salovey & Mayer, 1990, p. 189) was core to the original theorizing on EI, yet over the years has been neglected in research. Our meta-analytic findings suggest that rather than hitting the suggested "reset" button on EI theory (Dasborough et al, 2022, p. 7) because entrenched debates seem unresolvable, returning to the core dimensions of EI theory and reconsidering the distinction between self and other as targets of emotional abilities may pave a path forward.

Context as a Moderator in Emotional Intelligence Research

In line with Social Role Theory, we found some support for exaggerated gender differences where gender is more salient, such as in leadership roles (Manzi & Heilman, 2021). Gender differences in EI were also smaller in more recent data collections, consistent with increased flexibility regarding social roles. At the same time, other findings on the meso-level (i.e., male-dominated industry) were contrary to the reasoning put forward by Social Role

Theory. For example, gender differences in specific emotion abilities including emotion recognition and emotion regulation were smaller in male-dominated industries. We also found gender differences favoring women on general EI and abilities outside of the ability model were considerably larger for North American and European samples compared to the rest of the world.

These results echo research in personality finding that gender differences are most pronounced in North American and European cultures, contexts with less traditional sex role ideologies (Costa et al., 2001). In traditional cultures, differences between men and women may be externalized and attributed to the requirements of social roles and therefore become less indicative of the person themselves (Costa et al., 2001). Additionally, it may be the case that more masculine industries or macro-contexts represent "strong situations" which provide clear expectations on how to adequately behave (Meyer et al., 2020). If these contexts tend to have stronger situational requirements, this may limit individual gendered expressions of specific emotion abilities. Lastly, it may also be possible that in Non-Western cultures, for example, emotional perspectives may be de-emphasized (e.g., emotion regulation strategies such as suppression and avoidance are more prevalent; Song et al., 2024), thereby limiting the extent to which gender differences in emotion abilities can manifest themselves.

In line with the underlying socialization arguments of Social Role Theory, we found some support for the idea that gender differences differ by participant age. Specifically, gender differences in general EI and emotion recognition were associated with age such that gender differences were smaller in younger samples. These age-related patterns may reflect socialization processes, insofar as gendered emotion norms and role expectations may be reinforced with age. Further exploratory analyses showed that declines in gender differences over time were more pronounced in child samples than adult samples for general EI, emotion recognition, and

emotion regulation. This pattern is consistent with the possibility that shifts in gender norms may be reflected earlier in children's cohorts, though the design does not allow for causal conclusions. At the same time, biological explanations cannot be ruled out either, as developmental changes in neural, hormonal, and cognitive systems represent a compelling alternative explanation to gender differences associated with age. Rather than favoring a single account, these findings highlight the value of examining contextual moderators of gender differences in emotion abilities while underscoring the need for future research that can more directly examine the mechanisms underlying such age-related variation in gender differences in EI.

The combined results suggest that gender differences in EI can vary between contexts. Consequently, the extent to which differences in EI are present may not only depend on the features of the individual (including their age), but also on the situation/context (including its norms and social roles) at hand. Aligning with some scholarly voices that have begun to call for a contextualized approach to EI research (e.g., Fiori & Vesely-Maillefer, 2018; Jordan et al., 2010), we hope to invigorate future investigations that explore how contextual factors shape not only gender dynamics, but the presence and effects of emotion abilities in the workplace and beyond. Taking inspiration from research on gender and emotion, which has explored how power (e.g., Hecht & LaFrance, 1998) and culture (e.g., Fischer et al., 2004; Fischer & Manstead, 2000) shape emotional expressions, we call on EI scholars to continue these efforts in their domain of research. Through our large scale meta-analysis demonstrating robust moderation effects, we lay the groundwork for future research to increase nuance and specificity in examinations of gender and emotional intelligence.

Measurement Type as a Methodological Driver of Gender Differences in EI

A notable pattern in our findings concerns the discrepancy between performance-based and self-report measures of EI. Except for emotion understanding, women scored considerably higher than men on emotional abilities in performance-based measures compared to self-rated measures, to the extent that gender differences in emotion regulation vanish when participants self-report their abilities. This suggests that women may underestimate their actual abilities or that men may overestimate theirs, potentially reflecting gender norms and self-presentation pressures (e.g., reluctance to self-promote compared to pressure to appear competent). Such patterns are consistent with evidence that self-reported EI scores can be inflated or distorted by social desirability and self-presentation effects (e.g., Kluemper, 2008), potentially contributing to the misrepresentation of gender differences we observe. Although concerns about self-report measurement of EI have been raised frequently in the past (e.g. Ashkanasy & Daus, 2020; Dasborough et al, 2022), our findings show that self-reports may not just be unreliable and fraught with validity issues but also problematic because they systematically misrepresent gender differences in EI. Self-reports to measure EI disguise gender differences, implying that scientists and practitioners alike must be wary when utilizing them. Particularly in human resource practice, self-reports may perpetuate gender biases by awarding men with more opportunities, even though women may possess higher ability. Research and practice should therefore prioritize the development and broader adoption of validated performance-based measures across all EI abilities and targets, enabling more accurate estimation of individual differences in EI.

Limitations and Directions for Future Research

The current study aimed to comprehensively test gender differences across a large set of samples and measures. Nevertheless, performance measures do unfortunately not yet exist for all targets (i.e., self- and other-focused) of all emotion abilities. For example, our dataset included

no performance measure of self-focused emotion recognition ability, despite its conceptual distinctiveness from other-focused recognition. This gap not only limits the precision with which we can map potential gender differences but also highlights a broader measurement issue in the EI literature.

Although the current study was able to introduce two core tenants of gender studies (i.e., social and contextual implications of individual differences) to the field of EI research and test their meaningfulness across a broad array of studies, we are unable to make causal inferences. This may be of particular relevance in relation to the effect of contextual moderators, as we are unable to test whether context *causes* the extent to which men and women develop their EI. In line with Social Role Theory, we expect that contextual factors shape the extent to which each gender is confronted with demands to express their abilities. In line with this explanation, women in leadership roles may develop their emotion abilities as a resistance or legitimizing tactic in response to the salience of their gender (Vial et al., 2016). Yet, it could equally be the case that depending on one's gender and existing EI, people self-select for contexts such as leadership roles, which may attract men with lower EI abilities and women with higher EI abilities, increasing the magnitude of the gender difference for leaders compared to the general working population. Because we synthesized gender-difference effect sizes and many studies did not report gender-specific means, we cannot determine whether the moderation reflects differences in women's scores, men's scores, or both. Future work reporting gender-specific descriptive statistics (or using individual-participant data) is needed to disentangle contextual pressures from selection processes and better understand whether the observed moderation reflects changes in women's EI, men's EI, or both across contexts.

More broadly, our results clarify *where* gender differences in EI exist but not *why* they emerge. While our hypotheses primarily draw on socialization, emphasizing how early gendered experiences shape the development of emotional skills, biological mechanisms may also play a substantial role. For example, if differences in self- or other-focused emotion recognition stem from perceptual accuracy, physiological factors such as hormonal influences on signal detection could be central rather than solely the result of socialized experiences. Likewise, emotional vocabulary, though shaped by social context, is linked to broader cognitive functions that may influence recognition, understanding, and regulation simultaneously, making it difficult to isolate a single pathway. Because these abilities may share overlapping neurobiological and cognitive foundations, targeted interventions will only unfold their full potential when we disentangle the respective contributions of biological mechanisms (e.g., signal detection, pattern recognition, executive functioning) and socialization in future research.

Similarly, although we tested data collection year as a moderator and conducted exploratory analyses examining whether time trends differed by age group, measurement type, and geography, these analyses cannot uniquely separate year from age, generation, or time period. As a result, these represent potential alternative explanations for changes observed over time, and future work should aim to disentangle these through methods such as age, time period, and cohort effect analyses.

Constraints on Generality

The diversity of the samples in our meta-analysis, including 1,428 samples comprising of 609,278 child and adult participants from 76 countries, enhances the strength of our findings and supports the notion that our findings may be broadly generalizable across different groups and contexts. At the same time, we explicitly restricted our analysis to non-clinical samples. This

decision was made to avoid confounding gender effects in emotional intelligence with gender-specific disorder characteristics common in clinical populations. This restriction may have excluded healthy control groups from clinical studies that could have contributed relevant data, although our robustness checks and publication bias analyses suggest that our main conclusions are unlikely to be overturned by missing or excluded studies. Still, our conclusions may not directly extend to individuals with clinical diagnoses—a limitation that future research could address by specifically examining gender differences in EI within clinical contexts.

Another consideration in the interpretation of our findings may be that performance measures of EI are often costly and resource intensive. As a result, studies conducted in less resource-rich regions of the world, such as the Global South, may disproportionately rely on self-report measures rather than performance-based assessments. This potential bias could affect the consistency of conclusions drawn around EI measurement across different regions. However, our meta-analysis of primary studies from 76 countries takes a step forward towards offering a more comprehensive and globally representative analysis than previous efforts in the field.

Practical implications

The current findings partly confirm but also partly challenge prevailing assumptions that often attribute superior emotion abilities to women. For example, confirming expectations, we find that women indeed possess higher EI, but contrary to popular belief the disparity between men and women in self-focused emotion abilities is consistently and considerably smaller, with men even out-scoring women in self-focused emotion regulation. As such, disregarding the target of emotion abilities could lead women to find themselves in yet another conundrum: Even though women may have similar needs as men to train and expand their self-focused emotion abilities, they may be confronted with the idea that they ‘should’ possess higher emotion abilities

compared to their male colleagues, due to consistently higher scores in other-focused abilities obscuring the lack of difference between men and women for many self-focused abilities. Consequently, the belief that women generally possess higher emotion abilities may evolve to become another "emotional minefield" (Brescoll, 2016, p. 420), in which women must navigate incongruent expectations and outperform their male counterparts to be seen as equivalent.

At the same time, as women tend to be more skilled on other-focused emotion abilities, there may be a danger that female employees become double-burdened at work. Imagine a co-worker, Mark, easily being stressed at work and unable to manage his emotions adequately. Stereotypically, we may expect his female colleague, Maria, not only to manage her own reactions to Mark's agitation (e.g., being annoyed about his complaining or being increasingly nervous herself), but to also deal with Mark in an understanding and emotionally sensitive manner and become responsible for managing his stress. This example illustrates that gender dynamics may increase women's emotional demands at work, thereby possibly widening double standards. From a practical standpoint, it becomes imperative for organizational leaders to recognize women may be confronted with additional demands in performing other-focused emotional work. At the same time, an apparent proficiency of women in other-focused emotion abilities does not negate the possibility that women may benefit as much as men from support and training in self-focused emotion abilities.

Finally, organizations should be mindful that certain contexts at the micro level (i.e., leadership), meso level (i.e., male-dominated industries), or macro level (i.e., geographical region) may have the potential to change the relevance of EI and its subdimensions. Our findings suggest that the presence of EI and specific emotion abilities at work may not only be a function

of selecting the right people, but also situating them within contexts that support the relevance of EI at work, especially regarding gender differences.

CONCLUSION

Women seem to demonstrate significantly higher general EI as well as emotion recognition and understanding abilities, yet our findings emphasize that merely comparing a general EI score results in an oversimplification of gender differences, as the presence, magnitude, and direction of gender differences is contingent upon conceptual and methodological factors. Rather, our results speak to the fact that one cannot draw simple conclusions on *who* possesses EI or specific emotion abilities based on gender alone. Instead, *what* exactly is considered EI, *where* it is observed, and *how* it is measured significantly shapes the extent to which gender differences manifest as well as their strength. Columns in popular outlets like *Psychology Today*, *Forbes*, and others may thus be advised to tell a more nuanced story about how gender relates to navigating the emotional challenges that women and men face in life and at work together.
